Abstract

Inhaled nitric oxide (NO) has been reported to decrease the infarct size in cardiac ischemia reperfusion (I-R) injury. However, reactive nitrogen species (RNS) produced by NO causes myocardial dysfunction and injury. Since H₂ is reported to eliminate peroxynitrite, it was expected to reduce the adverse effects of NO. In mice, left anterior descending coronary artery ligation for 60 min followed by reperfusion was performed with inhaled NO (80 ppm), H₂ (2%), or NO + H₂, starting 5 min before reperfusion for 35 min. After 24 hrs, left ventricular function, the infarct size and area at risk (AAR) were assessed. Oxidative stress associated with reactive oxygen species (ROS) was evaluated by staining for 8-hydroxy-2'-deoxyguanosine and 4-hydroxy-2-nonenal, that associated with RNS by staining for nitrotyrosine, and neutrophil infiltration by staining for granulocyte receptor-1. The infarct size/AAR decreased with breathing NO or H₂ alone. NO inhalation plus H₂ reduced the infarct size/AAR, with significant interaction between the two, reducing ROS and neutrophil infiltration, and improved the cardiac function to normal levels. While nitrotyrosine staining was prominent after NO inhalation alone, it was eliminated after breathing a mixture of H₂ with NO. Preconditioning with NO significantly reduced the infarct size/AAR, but not preconditioning with H₂. In conclusion, breathing NO + H₂ during I-R reduced the infarct size and maintained cardiac function, and reduced the generation of myocardial nitrotyrosine associated with NO inhalation. Administration of NO + H₂ gases for

47 inhalation may be useful for planned coronary interventions or for the treatment of I-R injury.

51

52 Introduction

53 It is well-known that nitric oxide (NO) can produce both desirable and undesirable
54 effects (25, 26): NO has been reported to have both anti-inflammatory and cytotoxic effects.
55 The anti-inflammatory effects are presumably mediated by inhibition of platelet and
56 neutrophil activation *via* enhanced guanylate cyclase (17) and/or poly (ADP-ribose)
57 polymerase activity (3), and the cytotoxic effects are presumably mediated by reactive
58 nitrogen species (RNS), such as peroxynitrite generation (2), or from alternative pathways
59 including nitrite/H₂O₂/hemeperoxidase and transition metal-dependent mechanisms (20).

60 Tyrosine nitration caused by RNS or the alternative pathways increases the activity of
61 cytochrome C, fibrinogen and protein kinase C ϵ , and decreases the activity of mitochondrial
62 manganese superoxide dismutase, prostacyclin synthase, actin (20) and hemoxygenase (12).
63 It might have desirable effects in some specific situations (5), but the reactions of RNS or the
64 alternative pathways are strong and uncontrollable, and may cause cellular malfunction,
65 necrosis or apoptosis (2, 5), resulting in organ failure.

66 Inhaled NO has recently been reported to produce a wide range of extra-pulmonary
67 effects, such as inhibition of platelet and neutrophil activation, vasodilatation in ischemic
68 tissues, and so on (6, 15). Geury *et al.* then demonstrated that pretreatment with inhaled 10
69 ppm NO improved cardiac function after I-R (8), and Hataishi *et al.* reported that inhaled NO
70 decreased infarct size in mice subjected to cardiac ischemia followed by reperfusion (9).

71 They noted that NO inhalation of 40 or 80 ppm, but not 20 ppm decreased infarct size and
72 improved the cardiac function. In the pig, inhaled 80 ppm NO was reported to decrease
73 infarct size and improve cardiac function after myocardial I-R (13). These reports indicated
74 the possible clinical usefulness of NO inhalation during coronary intervention, and a phase 2
75 randomized clinical trial is now under way: Effects of nitric oxide for inhalation in
76 myocardial infarction size (NOMI), registered as NCT01398384 on July 18, 2011, refer to
77 <http://clinicaltrials.gov/ct2/show/NCT01398384>.

78 In 2008 Ohsawa *et al.* reported that hydrogen gas (H₂) has the potential to act as an
79 antioxidant (19). In their study, it was shown that H₂ selectively reduced the generation of
80 hydroxyl radicals and peroxynitrite, thereby protecting the cells against oxidant injury.
81 Furthermore, they studied an acute rat model in which oxidative stress was induced in the
82 brain by focal I-R, and inhaled H₂ gas markedly suppressed the associated brain injury. Thus,
83 it was suggested that administration of H₂ by inhalation may serve as an effective therapy for
84 I-R, and based on the ability of H₂ gas to rapidly diffuse across membranes, it can even
85 protect ischemic tissues against oxidative damage. Hayashida *et al.* investigated whether
86 inhaled H₂ gas conferred cardioprotection against myocardial I-R injury in rats, and in an *in*
87 *vivo* study, they observed that inhaled H₂ gas was rapidly transported to 'at risk' ischemic
88 myocardium before coronary blood flow was reestablished in the occluded region (10). In the
89 dogs, inhaled 1.3% H₂ gas was also reported to decrease infarct size after myocardial I-R (30).

These reports indicated the possible clinical usefulness of H₂ inhalation during coronary intervention, and a randomized clinical trial is now in preparation for recruiting. The safety and efficacy of inhalation of H₂ gas during PCI in patients with acute myocardial infarction, registered as UMIN000006825 on December 4, 2011.

Reasoning from these previous reports, we hypothesized that the inhibitory effect of NO on inflammation may be enhanced by eliminating highly reactive by-products of NO inhalation, such as peroxynitrite, by adding H₂ gas to inhaled NO gas. NO exerts potent inhibitory effects on platelets and neutrophils *via* activation of guanylate cyclase, and is expected to dilate small blood vessels, particularly in ischemic tissues.

The aim of the present study was to determine whether inhalation of NO combined with H₂ gas might be more effective at reducing infarct size and improving heart function in a murine model of myocardial I-R in comparison to inhalation of NO or H₂ alone.

Our findings indicate that breathing NO plus H₂ can reduce cardiac injury and augment recovery of the left ventricular function, by elimination of the nitrotyrosine produced by NO inhalation alone, and suggest the potential usefulness of employing a mixture of NO plus H₂ gases for inhalation during planned coronary interventions or for the treatment of I-R injury.

Materials and Methods

Experimental procedures (Fig. 1)

The animal experimental protocol was approved by the Animal Research Committee of Kitasato University School of Allied Health Sciences as well as of Medicine, and conformed to the “Guide for the Care and Use of Laboratory Animals” provided by the Institute for Laboratory Animal Research (National Academy of Sciences) in 1996; the animal facility met the standards of the American Association for Accreditation of Laboratory Animal Care.

Ten-week-old male C57BL/6J mice (body weight: 20-25 g) (CLEA Japan Inc, Tokyo, Japan) were anesthetized by intraperitoneal administration of pentobarbital (60 mg/kg) and ventilated (MiniVent, Hugo Sachs Elektronik, Harvard Apparatus, Holliston, MA, USA) at F_{IO₂} 0.2. Following thoracotomy, myocardial ischemia was induced by ligation of the left coronary artery at the level of the left atrial appendage for 60 min at F_{IO₂} 0.3, followed by reperfusion for 24 h. From 5 min before reperfusion to 30 min after reperfusion, 2% H₂, 80 ppm NO, or a mixture of NO (80 ppm, 0.008%) and H₂ (2%) was administered by inhalation. The thorax was then closed in layers, and animals were allowed to recover from anesthesia. Ventilation at F_{IO₂} 0.3 was continued until the mice were awake. After disconnecting from the ventilator and extubation of the trachea, mice were transferred into clean cages with free access to food and water.

NO was given at a concentration of 80 ppm, based upon a previous study on the cardioprotective effect of NO after myocardial I-R injury in mice, where NO inhalation of 40 or 80 ppm, but not 20 ppm, decreased infarct size and improved the cardiac function (9). H₂

was given at a concentration of 2%, based upon our dose-response experiment, where we confirmed that inhalation of 2% H₂ reduced murine myocardial I-R injury and that the effect did not significantly differ from the effect of breathing 3% H₂ (see Results shown below).

Previous studies have also reported that 2% H₂ inhalation was effective against I-R injury of the brain (19), liver (7) and heart (10) in rats; furthermore, it was confirmed that the H₂ levels in the blood and myocardium changed within a few minutes of starting and discontinuing 2% H₂ inhalation, and H₂ at a concentration of less than 4% in air is neither flammable nor combustible (1).

In an attempt to eliminate the variable effects of H₂ produced by the natural enterobacterial flora, animals were administered antibiotics for 4 days by mixing penicillin (1.25 mg/ml) and streptomycin (2 mg/ml) in the drinking water, and were denied access to food for 18 hr before the surgery, and mice not treated with the antibiotics and with free food access were also studied as a control. To exclude the possible effects of antibiotics themselves on the infarct size after I-R, the antibiotics were injected intramuscularly just before the I-R experiments, and ratios of area at risk (AAR) to the total area of the left ventricle (LV) and the infarct size to AAR (infarct size /AAR) were observed.

Dose response curve of breathing H₂ gas concentration and infarct size

The dose dependency of inhaled H₂ ranging from 1% to 3% H₂ on infarct size (see

below: **Measurement of myocardial infarct size**) in mice without treatment of antibiotics and fasting was examined in reference to the area at risk.

Measurement of H₂ concentration in the expired air of mice

Before surgery, expired H₂ concentrations were measured with an H₂ sensor (XP-3160, New Cosmos Electric Co Ltd., Osaka, Japan). Expired air of mice was forced to flow at 50 ml/min for 10 min into a gas-tight sampling bag made of aluminum. The expired air in the bag was then introduced into the H₂ sensor (Fig. 2A). We confirmed that the H₂ concentration in the expired air of antibiotics-treated mice was below the 1 ppm detection limit, while it was well over the detection limit in all of the antibiotics non-treated mice (Fig. 2B).

Echocardiography

Transthoracic echocardiography was performed with a commercially available echocardiography system (ProSound SDD-4000; ALOKA Co, Ltd, Tokyo, Japan), using a 4-14 MHz linear-array transducer. Closed-chest echocardiograms were obtained under anesthesia before the surgery and 24 h after reperfusion. The left ventricular ejection fraction (LVEF) was calculated using M-mode echocardiography.

Measurement of myocardial infarct size

At 24 h after reperfusion, the left coronary artery was re-ligated, and a tissue-marking dye (Evans blue, Wako Pure Chemical, Tokyo, Japan) was injected through the inferior *vena cava* to determine the area at risk (AAR). After the heart was harvested and placed in an agarose-containing well, the heart was sliced into 6 to 7 transverse slices of 1-mm thickness. The slices were placed in 1% 2,3,5-triphenyltetrazolium chloride solution in PBS for 10 min (first stain) and for 5 min (second stain), then washed with phosphate-buffered saline for 5 min and fixed with formalin for 10 min. The infarct zone remained pale yellow, whereas the viable areas stained deep red. Digital images of the slices were obtained. The area stained with neither Evans blue (area at risk, AAR) nor 2,3,5-triphenyltetrazolium chloride (infarct size) was measured on each slice image using an image software (Image J, NIH, USA), and summed. Ratios of AAR to the total area of the LV and the infarct size to AAR (infarct size /AAR) were calculated.

Immunohistochemical staining

Immunohistochemical staining of the heart tissues for 8-hydroxy-2'-deoxyguanosine (8-OHdG), 4-hydroxy-2-nonenal (4HNE) and nitrotyrosine, and staining for granulocyte receptor-1 (Gr-1) of the neutrophils in the heart at 24 h after reperfusion were carried out (at the Biopathology Institute Co., Ltd, Oita, Japan, for the 8-OHdG, 4HNE and nitrotyrosine stainings, and at Applied Medical Research Laboratory, Osaka, Japan, for the Gr-1 staining)

with randomized ID numbers, to ensure that the institute technicians were blind to the treatment allocation. Each harvested heart was fixed in Bouin's solution (picric acid-saturated solution : formalin : acetic acid = 15 : 5 : 1) for 3 days. Paraffin sections were prepared using a Young-type sliding microtome (Sakura Finetek Japan, Co., Ltd.), with a disposable microtome blade. The sections were 4 µm thick and mounted on silane-coated slides and deparaffinized with xylene, followed by stepwise changes of the ethanol concentration.

The slides for 8-OHdG, 4HNE and nitrotyrosine staining were treated with 1% hydrogen peroxide/methanol for 30 min to block endogenous peroxidase activity, and rinsed in Tris-buffered saline. Next, they were treated with 8% skimmed milk for 30 min. Anti-8-OHdG monoclonal antibody, anti-4HNE monoclonal antibody (each diluted 1:50, Japan Institute for the Control of Aging, Nikken Seil Co., Ltd : JaICA Japan) and anti-nitrotyrosine polyclonal antibody (diluted 1:200; 5 µg/mL diluted in phosphate-buffered saline containing 1% bovine serum albumin, Millipore, USA) in Tris-buffered saline were applied overnight to the sections in a moisture chamber at 4°C. They were then incubated in streptavidin-biotin-peroxidase solution according to the instructions for the strept ABComplex/HRP kit (Dako Japan Co., Ltd., Japan) for 8-OHdG and 4HNE staining, or according to the instructions for the MAX-PO kit (NICHIREI, Japan) for nitrotyrosine staining. The immunoreaction was visualized by the 3,3'- diaminobenzidine (DAB) reaction for 8-OHdG and 4HNE, and 3-amino-9-ethylcarbazole (AEC) for nitrotyrosine. The sections

were counterstained with hematoxylin.

The slides for Gr-1 were treated with 3% hydrogen peroxide for 10 min to block endogenous peroxidase activity, and rinsed in distilled water and Tris-buffered saline containing Tween 20. Next, they were treated with blocking solution containing 0.25% casein in PBS, stabilizing protein and 0.015 mol/L sodium azide (X0909, Dako Japan Co., Ltd.) for 5 min. Anti-mouse Gr-1 rat monoclonal antibody (diluted 1:200, MAB1037, R&D Systems, Inc., Minneapolis, MN) was applied to the sections overnight in a moisture chamber at 4°C. The slides were then incubated using the MAX-PO kit (NICHIREI, Japan) for 30 min. The immunoreaction was visualized by the DAB reaction, and the sections were counterstained with hematoxylin.

8-OHdG staining was quantified by counting the stained nuclei (brown) and all nuclei (blue and brown) in 5 fields ($240 \times 320 \mu\text{m}$) in each section for each animal (total of 3 animals). 4HNE and nitrotyrosine stainings were quantified by the ImageJ 1.40 g software. Brown color (the color of DAB staining) for 4HNE and red color (the color of AEC staining) for nitrotyrosine were extracted in 5 fields ($50 \times 50 \mu\text{m}$) in each section for each animal (total of 3 animals), and the stained pixel numbers were calculated. The Gr-1 staining was quantified by counting the stained cells (brown) in 2 fields ($1.9 \times 1.4 \text{ mm}$) in each section for each animal (total of 3 animals).

Preconditioning effect with either NO or H₂ breathing

To investigate the preconditioning effect with either NO or H₂ breathing on the infarct size, we placed anesthetized mice before the conventional 60-min occlusion of the left anterior coronary artery; 1) with no preconditioning maneuver as a control, 2) under 3 times 5-min occlusion (ischemic preconditioning) in 5-min intervals, 3) under 3 times 5-min exposure to 2% H₂ or 80 ppm NO (Fig. 7A). In all the procedure FIO₂ was fixed at 0.3.

Statistics

All data are presented as mean + SD. A one-way ANOVA with Tukey's *post hoc* test was used for multiple-group comparisons for all groups. A two-way ANOVA with replication was also used for comparison among the Control (antibiotics +), NO, H₂, and NO plus H₂ groups, to determine the two-factor interaction between the effects of NO and H₂. Additionally, a paired t-test was used to compare the results of echocardiography for mice between before and after I-R.

Results**Dose response curve of breathing H₂ gas concentration and infarct size**

Inhalation of 1 and 2% H₂ reduced murine myocardial I-R injury size and the effects did not significantly differ from the effect of breathing 3% H₂ (Fig. 3), as was reported in rats

(10).

Inhaled NO and/or H₂ decreased the infarct size after I-R injury

The ratio of AAR to left ventricle did not differ among groups (data not shown). The infarct size/AAR was significantly higher in mice administered antibiotics. Breathing NO, H₂, NO plus H₂ significantly decreased the infarct size/AAR. Furthermore, the infarct size/AAR in the mice that inhaled NO plus H₂ was significantly lower than that in those that inhaled NO alone (Fig. 4A&B), whereas the antibiotics *i.m.* injection just before the I-R experiments did not show worsening in the infarct size (Fig. 4C), with the same AAR/LV ratio (data not shown), indicating no direct protective effect of antibiotics on the cardiac I-R injury. The interaction between NO and H₂ was significant ($P=0.0052$).

The effects of the inhaled gases on the LVEF

Movement of the cardiac anterior wall of control mice was reduced after I-R, but that of mice inhaling NO plus H₂ remained unchanged (Fig. 4D&E). The LVEF after I-R in mice breathing NO plus H₂ was significantly improved as compared with that of control mice (Fig. 4E). The interaction between NO and H₂ was not significant ($P=0.4467$).

Immunohistochemical staining with antibodies against 8-hydroxy-2'-deoxyguanosine

(Fig. 5A&B)

The number of nuclei, calculated as a percentage of the total number of nuclei, that showed positive staining for 8-OHdG, was significantly decreased in mice that breathed NO, H₂, or NO plus H₂ as compared with that in the control mice. The number of positively stained nuclei in the mice that inhaled H₂ was significantly less than the value in mice that inhaled NO alone, but was not significantly different in mice inhaling NO plus H₂. The interaction between NO and H₂ was significant ($P<0.0001$).

Immunohistochemical staining with antibodies against 4-hydroxy-2-nonenal

Intense staining of the entire area for 4HNE was observed in the control groups (Fig. 5C). In the NO inhalation group, the stained area was reduced, and no staining was observed in the H₂ inhalation group or the NO plus H₂ inhalation group (Fig. 5D&E). The interaction between NO and H₂ was significant ($P=0.0006$).

Nitrotyrosine formation in the heart tissue

The nitrotyrosine-stained area expressed as a percentage of the total area in the region of interest was large in the control (both antibiotics – and +) groups and prominent in the NO inhalation group, whereas in the mice breathing NO plus H₂ the nitrotyrosine-staining was absent (Fig. 6A, B, C). The interaction between NO and H₂ was significant ($P<0.0001$).

Neutrophil infiltration in the heart tissue

The number of neutrophils in the region of interest in the slice was significantly decreased in the mice that inhaled NO or NO plus H₂ as compared with that in the control animals (+)(Fig6 D, E). The interaction between NO and H₂ was significant ($P=0.0225$).

Preconditioning effect with either NO or H₂ breathing

As was observed and reported as the ischemic preconditioning effect before myocardial I-R, preconditioning with NO breathing before the 60-min occlusion also had effects in decreasing the infarct size, whereas H₂ breathing did not decrease the infarct size (Fig.7B).

Discussion

The new findings after murine myocardial I-R in this study include: 1) Enterobacterial flora-derived H₂ slightly but significantly reduced myocardial infarct size; 2) NO plus H₂ breathing completely prevented the reduction of LVEF after I-R; 3) Either NO or H₂ breathing alone decreased infarct size. The reduction of infarct size was significantly greater in mice that inhaled NO plus H₂ than in those breathing NO alone; 4) Staining for ROS markers and neutrophils was reduced after NO and/or H₂ inhalation; 5) NO inhalation enlarged the myocardial staining area for nitrotyrosine, whereas H₂ inhalation completely

eliminated the staining for nitrotyrosine; 6) Preconditioning with NO before I-R decreased the infarct area, while preconditioning with H₂ did not.; 7) Repetitive two-way ANOVA revealed a significant interaction between the effects of NO and H₂ on the infarct size, ROS and nitrotyrosine production, and neutrophil infiltration.

The finding that the presence of enterobacterial flora caused a slight but significant reduction in infarct size suggests loss of H₂-producing enterobacteria is a risk factor for massive infarction after I-R in the heart, and possibly in the brain, and may be clinically significant. It has also been reported in humans that the composition of the gut flora varies among individuals (21) from H₂-dominant production to methane-dominant. A number of probiotic supplements are reported to be cardioprotective, while their effect may not be related to H₂ production; on the other hand, the cardioprotective effect of dietary fiber (23) may be related to H₂ production. Poorly digestible fiber debris is transported to the distal intestine, where anaerobes ferment the debris, and produce not only H₂, but also methane, hydrogen sulfide, and so on. Therefore, it cannot be excluded that antibiotics also eliminated potential other cardioprotective gases. It would be interesting to study the specific protective effect of H₂ by inoculating wild-type bacteria producing H₂ and gene-manipulated bacteria unable to produce H₂ after clearing the enteric bacteria, similar to the strategy employed for demonstrating the protective role of H₂-producing *E. coli* against Concanavalin A-induced hepatitis (11).

Although the persistent, but low-dose production of H₂ by enteric bacteria may contribute to reduction in the infarct size, or the dose-response relation for H₂ on the infarct size may be very steep, it should be noted that enterobacterial flora-derived gases were not sufficiently potent for cardioprotection after I-R injury, since inhalation of H₂ even in the presence of enterobacterial flora significantly reduced the infarct size (Fig. 3).

Nagasaka *et al.* have shown that the cardioprotective effects of inhaled NO require the presence of soluble guanylate cyclase- α_1 , and the results of their study suggested that bone marrow-derived cells are mediators of the ability of NO to attenuate cardiac I-R injury (18). Therefore, it is possible that a primary role of NO is to inhibit recruitment of leukocytes from blood stream to the heart. Their finding of the local effect of NO during myocardial I-R injury is in line with our finding of reduced neutrophil infiltration observed following NO inhalation, as well as of the *in vivo* preconditioning cardioprotective effect of NO-breathing before the induction of I-R injury on the infarct size.

Ohsawa *et al.* showed in an *in vitro* study that H₂ gas can reduce hydroxyl radicals. However, the reaction of H₂ with hydroxyl radicals is controversial. Since the half-life of hydroxyl radicals is short, 10⁻⁹ sec (24), and Wood and Gladwin noted that the hydroxyl radical is too short-lived to react with H₂, and will react with several cellular components before reacting with less abundant H₂ molecules (29). As compared to hydroxyl radicals, the half-life of peroxynitrite is long, 0.05-1 sec (24), and peroxynitrite has a greater chance to

337 react with H₂ in areas of I-R injury. H₂ molecules are very diffusible and may reach ischemic
338 tissues even before reperfusion (10). During ischemia and reperfusion, they will eliminate
339 peroxynitrite (and possibly hydroxyl radicals), thereby suppressing inflammation and cellular
340 apoptosis. Concerning the mechanism of the effects of H₂ gas, other possible sites of action
341 of H₂ have been suggested, such as induction of hemoxygenase 1 (4) and heat shock protein
342 (28). These possibilities need to be further investigated. These possibilities should further be
343 investigated.

344 A comparison of the effects of inhaled NO with those of inhaled H₂ in our study revealed
345 that they exerted equivalent cardioprotective effect, both in terms of improving the cardiac
346 function and reducing the infarct size. The ROS markers, 8-OHdG and 4HNE, were similarly
347 eliminated. A major difference between the effects of NO and H₂ breathing is the production
348 of nitrotyrosine in the tissue affected by I-R injury in NO breathing. The increased amount of
349 nitrotyrosine produced by inhaled NO suggests that some adverse effects on signal trafficking
350 and cellular function may occur sooner or later by the RNS reactions with the tyrosine at the
351 active site of vital enzymes and cellular components.

352 It should be noted that we used the maximal concentration of NO, 80 ppm, as had been
353 reported to be effective in the protection of heart against I-R injury, and furthermore we
354 placed the mice under the minimal contribution of enterobacterial flora-derived H₂ by
355 administering antibiotics with fasting. It is possible that less NO inhalation with more

enterobacterial flora-derived H₂ might potentially protect heart from I-R injury, but even in that case H₂ inhalation would minimize the potential risk caused by nitrotyrosine production.

Other potential methods to reduce peroxynitrite production while maintaining the beneficial effects of inhaled NO could be to use a peroxynitrite decomposition catalyst (14, 27) or increase the cGMP concentration in the cells by using a soluble guanylyl cyclase activator(22) or phosphodiesterase-5 inhibitor (16), since these enhancers of NO effects via cGMP induction may enable reduction of the inhaled NO concentration, thereby decreasing peroxynitrite formation and minimizing the adverse effects of NO inhalation.

One of the limitations of this *in vivo* study was that young male mice were used for this study, while myocardial I-R injury typically occurs in older individuals with comorbid risk factors such as diabetes and atherosclerosis; furthermore, many cardioprotective interventions that are effective in younger animals are not effective in older animals or in the presence of risk factors, a phenomenon that may be related to chronic oxidative stress (31). Therefore, it will be important to verify our study findings in older mice, and in relation to enterobacterial flora-derived H₂.

In conclusion, inhaled NO suppresses the inflammation in I-R tissues, and H₂ eliminates the adverse by-products of NO exposure, peroxynitrite. Thus, our study supports the view that NO and H₂ are suggestive partners that can be used as a mixture for breathing during coronary interventions.

Figure legends

Fig. 1. Experimental procedure.

Myocardial ischemia was induced by transient occlusion of the left anterior descending coronary artery. After 60 min of ischemia, the coronary artery was reperfused and the thorax was closed. Commencing 5 minutes before reperfusion, 2% H₂, 80 ppm (=0.008%) NO, or NO (80 ppm) and H₂ (2%) was added to inspiratory gas at FIO₂ 0.3 exposure from 5 min before reperfusion and during the initial 30 min of reperfusion. The mouse was sacrificed and the heart was harvested and evaluated 24 hrs after reperfusion.

Fig. 2. Measurement of H₂ concentration in the expired air of mice

A: Mice were placed in a cage of 500ml. Expired air of mice was forced to flow at 50 ml/min into a sampling bag for 10 min. B: The concentration of H₂ in expired air of mice, which were given antibiotics and were treated with fasting, decreased under the limit of detection.

Fig. 3. Dose response curve of breathing H₂ gas concentration and infarct size.

The dose dependency of inhaled H₂ on infarct size in reference to the area at risk showed that inhalation of 1 and 2% H₂ reduced murine myocardial I-R injury size and that the effects did not significantly differ from the effect of breathing 3% H₂.

Fig. 4. Effects of the inhaled gas species on infarct size and heart function.

A: Representative cross sections after triphenyltetrazolium chloride staining in each group. B, top: The ratio of the area at risk (AAR) to the total area of the left ventricle (LV), AAR/LV, did not differ among the groups. B: The ratio of infarct size to AAR, infarct size/AAR, was significantly larger in mice given antibiotics. Breathing NO, H₂, and NO plus H₂ significantly decreased the infarct size/AAR. The infarct size/AAR in mice that inhaled NO plus H₂ was significantly lower than that of the mice that breathed NO only. C: To exclude the possible direct protective effects of antibiotics on the infarct size after I-R, the antibiotics were given *p.o.* as in the protocol (Fig.1) or injected intramuscularly (*i.m.*) just before the I-R experiments, and no worsening in the infarct size by *i.m.* injection has been observed, indicating no direct effect of antibiotics on the infarct size. D: Typical echocardiographic image at 24 hrs after I-R. E: LVEF of mice before and at 24 hrs after I-R. LVEF was significantly decreased at 24 hrs after I-R, except in mice that inhaled NO plus H₂. LVEF after I-R in the mice inhaling NO plus H₂ was significantly improved to that in the control mice, while that in the mice inhaling either NO or H₂ alone was significantly less than that in the control mice. * $P < 0.05$ differs vs. control. # $P < 0.05$ differs vs. NO inhalation. Data are presented as mean + SD.

Fig. 5. Immunohistochemical staining for 8-hydroxy-2'-deoxyguanosine and

535 4-hydroxy-2-nonenal.

536 A: Nuclei stained blue with hematoxylin and stained brown by the DAB reaction using

537 primary antibody against 8-hydroxy-2'-deoxyguanosine. B: the number of

538 8-hydroxy-2'-deoxyguanosine-immunoreactive nuclei, expressed as a percentage of the total

539 number of nuclei in the region of interest in the slice, was significantly decreased in the mice

540 that inhaled NO, H₂, or NO plus H₂. C: Nuclei stained blue with hematoxylin and cells

541 stained brown by the DAB reaction using antibody against 4-hydroxy-2-nonenal. D:

542 Histogram of the brown color of each image extracted by color deconvolution. The tone level

543 of the brown color component of each pixel was presented on a scale of 0 (brown) to 255

544 (white). E: The 4-hydroxy-2-nonenal-immunoreactive area was expressed as a percentage of

545 the total area in the region of interest of the slice. Intense staining for 4-hydroxy-2-nonenal

546 was observed in the entire infarct area in control groups. Inhalation of NO reduced the stained

547 area as compared with that of control group. The stained area was eliminated in both the H₂

548 group and the H₂ plus NO group. Data are presented as mean + SD.

549

550 Fig. 6. Immunohistochemical staining for nitrotyrosine and neutrophils.

551 A: Nuclei stained blue with hematoxylin and cells stained red by the AEC reaction using

552 antibody against with nitrotyrosine. B: Histogram of the red color regions of each image

553 extracted by color deconvolution. The tone level of the red color component of each pixel

was presented on a scale of 0 (red) to 255 (white). C: The nitrotyrosine-immunoreactive area (number of pixels of red color) was expressed as a percentage of the total area covered by the cells (number of pixels covered by the cells) in each section. The nitrotyrosine-immunoreactive area was significantly larger in the NO group than in other groups. Nitrotyrosine-immunostaining was completely absent in both the H₂ group and NO plus H₂ groups. D: Neutrophils stained brown by the DAB reaction after incubation with a primary antibody against granulocyte receptor-1, and the nuclei stained blue with hematoxylin. E: The number of neutrophils in the region of interest in the slice was significantly decreased in the mice that inhaled NO or NO plus H₂ as compared with that in the control animals (+).

Data are presented as mean + SD.

Fig.7 Preconditioning effect with either NO or H₂ breathing

A: Ischemic preconditioning effect as well as preconditioning effect with NO or H₂ breathing on infarction size after I-R injury was investigated. The coronary artery was occluded or mice breathed NO or H₂ for 5-min in 5-min intervals 3 times before the conventional 60-min occlusion of the left anterior coronary artery. B: Preconditioning with NO breathing before the 60-min occlusion also had effects in decreasing the infarct size, whereas preconditioning with H₂ breathing did not decrease the infarct size.
